1. Introduction

Semiconductor light sources emitting in the deep ultra-violet (DUV) region have numerous applications such as sterilization, water/air purification, optical imaging systems, spectroscopy, and high density storage systems. III-nitrides are excellent candidates because of their interesting properties which include tunable band gap that covers the UV spectral range, and also include thermal and chemical stability. However, compared with InGaN-based visible laser diodes or light emitting diodes (LEDs), the efficiency which was measured to be \( \sim 1\% \) at room temperature even when V-pit density was increased from \( 7 \times 10^7 \text{ cm}^{-2} \) to \( 2 \times 10^8 \text{ cm}^{-2} \). The results help to understand the origin, propagation and influences of the typical defects in AlGaN MQWs grown on AlN/Al2O3 templates which may lead to further improvement of the performance of DUV devices.

10-period Al\(_{0.57}\)Ga\(_{0.43}\)N/Al\(_{0.38}\)Ga\(_{0.62}\)N multi-quantum wells (MQWs) were grown on a relaxed Al\(_{0.58}\)Ga\(_{0.42}\)N buffer on AlN templates on sapphire. The threading dislocations and V-pits were characterized and their origin is discussed. The influence of V-pits on the structural quality of the MQWs and on optical emission at 280 nm was analyzed. It was observed that near-surface V-pits were always associated with grain boundaries consisting of edge threading dislocations originating from the AlN/Al\(_2\)O\(_3\) interface. Although the high density of V-pits disrupted MQWs growth, it did not affect the internal quantum efficiency which was measured to be \( \sim 1\% \) at room temperature even when V-pit density was increased from \( 7 \times 10^7 \text{ cm}^{-2} \) to \( 2 \times 10^8 \text{ cm}^{-2} \). The results help to understand the origin, propagation and influences of the defects on DUV emission at 280 nm.
2. Experiments

The growth was performed in an MOVPE T-shape reactor [18] at 1000 °C under 100 Torr. Hydrogen was used as carrier gas. Trimethyl-aluminum (TMAI), trimethyl-gallium (TMGa) and NH₃ were used as precursors for aluminum, gallium and nitrogen, respectively. Two types of AlN templates grown on c-axis sapphire [20] were used as substrates, one with high dislocation density (template 1) and the other with low dislocation density (template 2). 10-period AlₓGaₙ₋ₓN/Al₀.₃₈Ga₀.₆₂N MQWs were grown on relaxed Al₀.₅₈Ga₀.₄₂N buffer on these two types of AlN templates [19]. The samples grown on the same type of template in different runs have comparable defect density, which confirmed reproducibility. Identical or similar structures grown on different types of templates (template 1 and template 2) have significant difference in V-pit density and they were chosen in order to study the influences of defects on optical properties of MQWs emitting in the deep UV region.

The structural characterizations of the MQWs were carried out using high-resolution X-ray diffraction (XRD) measurements in a Panalytical X’pert Pro MRD system with Cu Kα radiation. Cross-sections and plan-views of the samples were investigated by high-angle annular dark field scanning transmission electron microscopy (HAADF-STEM) and high resolution transmission electron microscopy (HRTEM), and the TEM lamellas were prepared using focused ion beam (FIB) etching. Surface morphology was characterized by scanning electron microscopy (SEM). The optical properties were investigated by transmission, temperature-dependent photoluminescence (PL) and depth-resolved cathodoluminescence (CL). The PL measurements were done from 5 K to 275 K with a cw laser (266 nm) and a weak excitation power of ~1 W/cm² in order to maintain the thermal equilibrium condition and to avoid saturation of emission intensity. The spot diameter of PL is around 100 μm at maximum. For transmission measurements, the size of probed area is around 0.02 mm².

3. Results and discussions

10-period Al₀.₅₇Ga₀.₄₃N (10 nm)/Al₀.₃₈Ga₀.₆₂N (1.5 nm) MQWs grown on a relaxed Al₀.₅₈Ga₀.₄₂N buffer (~ 630 nm) were designed to preserve E-field⊥c polarized emission (which will be referred to as TE polarization) at 280 nm and work around the problem related to switching of the valence band state symmetry for high aluminum compositions, and more details can be found in Ref. [19]. The sample grown on template 1 is labeled as sample 1 and the other grown on template 2 is labeled as sample 2. Fig. 1 shows (0 0 0 2) 2θ-ω scans of both samples. Satellite diffraction peaks (SL) can be observed which indicate good periodicity of MQWs. Based on (1 1 −2 4) reciprocal space mapping, the buffer containing 0.58 (± 0.01) Al has 70% relaxation. According to the fittings, the wells of sample 1 contain 0.38 (± 0.015) Al with thickness of 1.5 nm (± 0.2 nm), while the barriers contain 0.58 (± 0.015) Al with thickness of 10.3 nm (± 0.2 nm). For the sample 2, the wells contain 0.38 (± 0.015) Al with thickness of 1.3 nm (± 0.2 nm), while the barriers contain 0.58 (± 0.015) Al with thickness of 9.3 nm (± 0.2 nm). The slight difference of thicknesses may be due to unintentional drift between the runs.

In order to estimate threading dislocation (TD) densities in the samples, a series of skew symmetric ω scans were done to

![Fig. 1. (0 0 0 2) 2θ-ω scans for (a) sample 1 and (b) sample 2 along with fitting.](image-url)
separate tilt angle (screw threading dislocations) and twist angle (edge threading dislocations), as expressed in Eq. (1), which is particularly useful for layers with high defect densities such as AlN [21,22]:

\[
\beta^2 = (\beta_{\text{twist}}^2 - \beta_{\text{tilt}}^2) \sin^2 \chi + \beta_{\text{tilt}}^2
\]

where \( \beta \) is the full width at half maximum (FWHM) angle and \( \chi \) is the inclination angle between the reciprocal lattice vector and the \( (0 0 0 1) \) surface normal.

Then the screw threading dislocation and edge threading dislocation densities may be estimated by Eq. (2):

\[
N_{\text{screw}} = \beta_{\text{tilt}}^2 / (4.35 \times b_c^2)
\]

\[
N_{\text{edge}} = \beta_{\text{twist}}^2 / (4.35 \times b_a^2)
\]

where \( \beta_{\text{tilt}} \) and \( \beta_{\text{twist}} \) are the tilt and twist spreads (FWHMs). The Burgers vector of c-type TD (\( b_c \)) is 0.4982 nm for AlN and 0.5067 nm for Al\(_{0.58}\)Ga\(_{0.42}\)N, and the Burgers vector of a-type TD (\( b_a \)) is 0.3112 nm for AlN and 0.3144 nm for Al\(_{0.58}\)Ga\(_{0.42}\)N.

The FWHM angles measured for AlN templates and AlGaN layers (buffer + MQWs) of two samples are shown in Fig. 2. The screw and edge TD densities calculated by the method above are shown in Table 1. For both samples, extra TDs were not generated within the relaxed AlGaN buffer layers. The AlN template used for sample 1 exhibits 3 times higher screw and edge TD densities than that used for sample 2, and the density of pits on the surface is around 30 times higher as seen in SEM images. These holes have hexagonal shape, and the ultra-high density of the holes in sample 1 leads to the surface inhomogeneities. On the contrary, sample 2 with much lower pit density has a flat surface (apart from holes) with root-mean square roughness (RMS) as small as 0.5 nm by atomic force microscope measurements.

In order to study the origin of these holes and their influences on the MQW growth, cross-section HAADF-STEM was performed and images of sample 1 are shown in Fig. 3. In the flat area of Fig. 3(a), the 10-period MQWs have good uniformity and periodicity. The thicknesses of barriers and wells agree with XRD fitting results. In Fig. 3(b), it is clearly observed that the threading dislocations originate from the nucleation layer at the interface of AlN and sapphire. After a certain thickness, the dislocations are mostly aligned along the \([0 0 0 1]\) axis. These dislocations can form low angle grain boundaries and lead to a twist of the lattice. The V-pits near the surface are always associated to these grain boundaries. Fig. 3 (c) shows the plan-view HRTEM image of the AlN template in which

\[
\sum_{\text{FWHM determination and linear fitting lead to an estimated error of } \pm 8\% \text{ for threading dislocations} \text{ for sample } 1 \text{ and sample } 2.}
\]

some grains with size from 50 to several hundred nanometers can be identified. The atomic resolution STEM image with higher magnification is shown in Fig. 3(d) to get rid of the Moiré fringes. These grains are separated by low-angle boundaries with small misorientation of 1–2°. During regrowth of AlGaN layers and MQWs, the threading dislocations and grain boundaries propagate into the following layers and penetrate the whole structure.

By looking into the V-shape defects in Fig. 3(e) with higher magnification, it is seen that the apex of the holes is connected to extended defects which are c-axis oriented and inherited from the AlN layer. These lines should be edge threading dislocations or mixed threading dislocations since the image is taken along the [1 1 2 0] zone axis. The possible cause of V-defects could be that impurities tend to segregate into dislocations, which may locally impede growth resulting in a small indentation. Once the facets of slow growth planes are formed due to these indentations, a V-pit can be generated [23, 24]. Compared with the sample 2, the sample 1 has higher edge threading dislocation density which increases the probability for forming pits.
As shown in Fig. 3(e) and 3(f), the facets of the holes are inclined about 62° to the c plane, which corresponds to (1 0 − 1 1) facets. The growth rate on these planes is much slower than on the c plane [23,24], so a V-shape hollow hole is formed. Fig. 3(f) is an example of 4-period MQWs grown for investigating the sidewall growth in a V-pit. On the V-pit sidewall which is near c-plane surface, the weak contrast of QWs can be observed. Both the thickness of wells and barriers here are almost one third of the ones grown on the c plane. This small area of QW growth on the sidewall may lead to some additional emission wavelengths with weak intensity giving rise to main peak broadness. In the area closer to the center of the hole, the wells are merged into the barriers and cannot be identified. The V-pits interrupt the super-lattice growth and may lead to non-uniformity of 2D MQW properties.

The optical properties of sample 1 and sample 2 were investigated. Fig. 4(a) shows the PL at 80 K and transmission spectrum at 77 K. Sample 1 shows a well-defined emission at 282 nm. The absorption edge of the wells is at 281 nm and absorption edge of barriers is at 260 nm, which is in a good agreement with the design and with the compositions determined by XRD. For the sample 2, the PL emission is at 278 nm while absorption edge is 275 nm for the wells and 260 nm for the barriers. The absorption edge of sample 2 is 6 nm blue-shifted which can be due to the thinner wells according to XRD fitting. The emission of sample 1 has full width at half maximum (FWHM) of 12.5 nm, while sample 2 has FWHM of 7.2 nm indicating a lower inhomogeneous broadening, which is consistent with transmission measurements. The broadening of emission peak in sample 1 can be caused by the local variations of thickness or composition in MQWs which occurred in the high density of V-pit sidewalls near the c-plane surface, as shown in Fig. 3(f).

Fig. 5 shows the PL integrated intensity as function of the inverse of temperature as well as Arrhenius fitting curves. The fitting equation is as follows [25]:

\[
I_{PL}(T) = \frac{I_0}{1 + A \exp\left(-\frac{E_A}{kT}\right) + B \exp\left(-\frac{E_B}{kT}\right)}
\]

where \(I\) is the integrated intensity with arbitrary unit, and \(I_0\) is a fitting parameter which can be seen as the integrated intensity when \(T\) is close to 0 K. \(A\) and \(B\) are fitting constants for two non-radiative recombination channels: the first mechanism (channel \(A\)) is for detrapping of localized excitons which dominates in the low temperature range, and the second (channel \(B\)) is for escaping out of the wells which dominates in the high temperature range. \(E_A\) and \(E_B\) are corresponding activation energies for those two paths.

Fig. 4. Transmission spectra at 77 K and PL at 80 K for (a) sample 1 and (b) sample 2.
of carrier escape from localized states into the non-radiative recombination centers. The internal quantum efficiency (IQE) can be compared by defining IQE = I(T)/I_0 [26,27]. In this case, the efficiency is assumed to be 100% at 5 K, which is reasonable since the intensity was almost constant (defined as I_0) in the temperature range of 5–50 K indicating almost no influence of non-radiative process in this range.

Based on Arrhenius equation fitting, sample 1 has 29 meV for EA and 96 meV for EB. Sample 2 has 49 meV for EA and 150 meV for EB. There is a larger energy barrier of nonradiative processes for sample 2.

Fig. 5(c) shows the IQE variation with the temperature for the two samples based on Arrhenius equation. At 77 K, the IQE of sample 1 decreased to 80% while sample 2 still has an IQE of 94%. This can be explained by the increased concentration of nonradiative centers caused by higher dislocation density in sample 1 [28,29]. In the high temperature range, the IQE of both samples drops dramatically due to the high level of dislocation densities. Near room temperature, the error bar becomes large because emission intensity is weak and the residual laser contribution to the luminescence is not negligible. But it should be noted that these pits may lead to current leakage as has been observed in InGaN MQWs [10] and to lower external emission efficiency of current-injected LEDs or lasers [15].

The CL spectra shown in Fig. 6 were collected by scanning over an area ~8 μm × 11 μm at room temperature, giving the average information of the sample (including flat areas and rough areas with pits). The measurements were done under excitation from 3 keV to 7 keV. Fig. 6(a) and (b) shows the spectra under 7 keV which corresponds to a penetration depth of the electron beam of typically 90 nm. Emission from wells is located at 286 nm with FWHM of 16 nm for sample 1 and at 276 nm with FWHM of 13 nm for sample 2. Besides the emission from MQWs, both samples show weak defect band emission at 333 nm. By comparing the emission intensity from the wells and the defect band, the ratio of I_{MQWs}/I_{defects} is 4.5 for sample 1 and 24 for sample 2 which may be attributed to lower dislocation density and the existence of more flat surface area with good quality QWs which can interact with the electron beam. The comparison of FWHM between the two

---

**Fig. 5.** PL integrated intensity as function of temperature (with a cw laser and a weak excitation of ~1 W/cm²) and Arrhenius fitting for (a) sample 1 and (b) sample 2; (c) is the curve of IQE versus temperature based on Arrhenius equation fitting.
samples in Fig. 6(c) confirms again the higher emission uniformity of sample 2 with fewer V-pits.

4. Conclusions

The threading dislocations and V-shape pits in an AlGaN MQW structure grown on AlN templates for emission at 280 nm were characterized by different methods. Near surface pits were associated with grain boundaries in the AlN template consisting of edge threading dislocations from the AlN/Al2O3 interface. The density of V-pits did not play an important role in IQE of MQWs by PL measurements, but the pits disrupted MQW growth and may have an effect on the homogeneity of emission. The results help to understand the origin and propagation of typical defects in AlGaN MQWs grown on AlN templates and their influences on structural quality and optical properties of MQWs for DUV emission, as an indispensable step for further improving the efficiency of the DUV devices.
